Active noise experienced by a passive particle trapped in an active bath

Simin Ye, Peng Liu, Fangfu Ye, Ke Chen and Mingcheng Yang

We study the properties of active noise experienced by a passive particle harmonically trapped in an active bath. The active bath is either explicitly simulated by an ensemble of active Brownian particles or abstractly represented by an active colored noise in theory. Assuming the equivalence of the two descriptions of the active bath, the active noise in the simulation system, which is directly extracted by fitting theoretical predictions to simulation measurements, is shown to depend on the constraint suffered by the passive tracer. This scenario is in significant contrast to the case of thermal noise that is independent of external trap potentials. The constraint dependence of active noise arises from the fact that the persistent force on the passive particle from the active bath can be influenced by the particle relaxation dynamics. Moreover, due to the interplay between the active collisions and particle relaxation dynamics, the effective temperature of the passive tracer quantified as the ratio of fluctuation to dissipation increases as the constraint strengthens, while the average potential and kinetic energies of the passive particle both decrease.

1 Introduction

Active colloids consist of mesoscale self-propelled units that are able to locally convert stored or ambient energy into their persistent locomotion. Prominent examples include colonies of bacteria and synthetic microswimmers. Due to being intrinsically out of equilibrium, active colloidal suspensions can serve as an active bath that can profoundly impact the structure and dynamics of immersed passive objects. For instance, an active bath can greatly deform flexible macromolecules or give rise to unusual effective interactions between passive objects or unexpected self-assemblies. Moreover, an active bath can dramatically enhance the diffusion of passive tracers by orders of magnitude compared to thermal cases, and can drive a directed motion of asymmetric objects. These phenomena are fundamentally different from equilibrium thermal baths. Despite their important differences, the generalization of important physical concepts and relations (such as temperature, pressure, depletion force, equation of state or fluctuation relation) from thermal to active bath has recently attracted considerable attention.

Neglecting the internal degrees of freedom, the effect of an equilibrium thermal bath on a tracer particle can be well described by thermal stochastic force and friction, which are connected by the fluctuation dissipation theorem. For a given system, the thermal noise on a tracer particle is uniquely determined by the properties of the thermal bath, independent of external conditions such as external constraints, forces or boundaries. Similarly, one may characterize an active bath by introducing a time-correlated active noise that takes into account the persistent collisions between the passive tracers and active microswimmers. Such active noise no longer follows the fluctuation-dissipation relation, thus breaking the detailed balance. This minimal model has recently been successfully applied to a harmonically confined passive colloidal particle in an active bath, which constitutes a paradigm to study nonequilibrium statistical physics. The active noise, although artificially imposed in theories, can be directly extracted from colloidal experiments or simulations. It is implicitly assumed that the active noise is an intrinsic feature of the active bath, similar to the thermal noise in equilibrium, and is completely determined by the active swimmers, the passive tracers and their interactions. Recent studies, however, suggest that active pressure depends on the details of external boundary walls and active depletion force drastically changes with external constraints. These observations raise the fundamental questions of whether and how external conditions influence the active noise.
In this paper, we study the dynamics of a passive particle suspended in an active bath, trapped by harmonic potentials of various stiffness, using computer simulations and theoretical analyses. In simulations, the active bath is modelled by an ensemble of active Brownian particles (ABPs); and in theory, the active bath is described by an active noise. By fitting the theoretical prediction to the simulation measurement, we find that the extracted active noise, both its magnitude and correlation time, sensitively depends on the constraint experienced by the passive particle, in contrast to its thermal counterpart. An intuitive explanation for this constraint dependence of active noise is that the external trapping influences the intensity of collisions between the tracer and active particles. The theoretical model with a constraint-dependent active noise quantitatively reproduces the mean potential energy of the tracer particle measured in simulations. Furthermore, we show that three widely used effective temperatures (separately quantified as the ratio of fluctuation to dissipation, and the average potential and kinetic energies of the passive particle) all change significantly with the external constraint, but in different manners. Our results demonstrate that the active noise experienced by a confined passive tracer cannot be treated as an intrinsic physical quantity of the active bath, and a single constant effective temperature is not sufficient to describe the tracer behaviors.

2 Simulation and theory

Simulation

The simulation is performed by considering a 2D system consisting of 2000 small ABPs with a diameter of $\sigma_s$ and a mass of $m$, and one large passive tracer with a diameter of $\sigma_l = 3\sigma_s$ and a mass of $M$, as sketched in Fig. 1(a). The interactions between the particles are modelled by a repulsive Lennard-Jones-type potential, $U(r) = 4\varepsilon \left[ \left( \frac{\sigma}{r} \right)^{12} - \left( \frac{\sigma}{r} \right)^6 \right] + \varepsilon$, for $r \leq 2^{\frac{1}{6}} \sigma$. The interaction diameter between passive and active particles is taken as $\frac{1}{2} (\sigma_s + \sigma_l)$. The translational motion of the active particles evolves according to the underdamped Langevin equation,

$$m\ddot{x} = -\gamma_s x + F_d + F_t + \xi,$$

with $F_d$ being the self-propulsion force, $F_t$ being the steric interaction between particles, $\gamma_s$ being the friction coefficient, and $\xi$ being Gaussian distributed stochastic force with zero mean and variance $\langle \xi(t)\xi(t') \rangle = 2k_BT\gamma_s\delta(t-t')$ ($\sigma$ and $\beta$ represent Cartesian components). In the simulations, we always take $F_d/\gamma_s k_BT = 20$, which is comparable to the value of the swimming *E. coli* bacteria in experiments. The Brownian rotation of the active particles is similarly simulated with the rotational friction coefficient $\gamma_r = \frac{1}{3}\gamma_s^2$.

The translational motion of the passive particle also follows eqn (1) with the frictional coefficient $\gamma_l = 3\gamma_s$ and $F_d = 0$. Additionally, the passive tracer is constrained by a harmonic potential $U_{\text{ext}}(r) = \frac{1}{2}kr^2$, with $r$ being the tracer displacement from the trap center and $k$ being the trap stiffness. A typical trajectory of the large passive particle trapped in the active bath is plotted in Fig. 1(b). In the simulations, we use the under-damped (instead of overdamped) Langevin equation in order to quantify the kinetic energy of the passive tracer.

Theory

The effect of the active bath on the passive tracer can be theoretically captured by including an active colored noise term in the traditional overdamped Langevin equation,$^{43-49}$

$$\dot{x} = \mu f(x) + \eta + \eta_A,$$

with $f(x) = -kr$ being the restoring force from the external trap, $\mu$ being the tracer mobility, $\eta$ being the thermal noise and $\eta_A$ being the active noise. The variance of the thermal noise reads $\langle \eta(t)\eta(t') \rangle = 2D_T\delta(t-t')$ with $D_T$ being the diffusion coefficient of the passive tracer originating from the thermal bath. The variance of the active noise is $\langle \eta_A^2(t)\eta_A^2(t') \rangle = D_A\delta(t-t') \exp(-|t-t'|/\tau)$, where $D_A$ denotes the active contribution to the tracer diffusion coefficient characterizing the strength of the active fluctuations and $\tau$ is the correlation time of the active fluctuations. A similar coarse-grained model has been widely used to describe active colloidal particles themselves,$^{55-60}$ where $f(x)$ corresponds to the interactions between the active particles.

In previous work based on eqn (2),$^{43,45-49}$ the diffusion coefficient $D_T$ is taken as $D_T = k_BT$, with the mobility $\mu$ only originating from the thermal bath. This description does not consider the active friction contributed by the couplings between the tracer and active particles,$^{49}$ and is only valid in the dilute limit for active baths.$^{50}$ For semidilute or concentrated active particle solutions, $\mu$ needs to include both the thermal and active contributions, so that the average friction is balanced by the external force, i.e., $\langle f \rangle/\mu = \langle f(x) \rangle$ (the friction memory kernel remains instantaneous$^{44}$). In these cases, the thermal diffusion coefficient $D_T$ does not obey the Einstein relation $D_T = k_BT$, since $\mu$ now contains the active contributions. In simulations, $D_T$ can be measured as the diffusion coefficient of the tracer in the same active bath when the activities of the constituent swimmers are switched off, such that $D_A$ exclusively corresponds to the active diffusion following its definition.
Following ref. 43, the mean square displacement (MSD) of the passive tracer in the x (or y) direction can be calculated from eqn (2) as

$$\left\langle \Delta x^2(t) \right\rangle = \frac{2D_T}{\mu k} (1 - e^{-\mu k t}) + \frac{2D_A}{\mu k} (1 - e^{-\mu k t} - \mu k t (1 - e^{-\mu k t})) \quad (3)$$

Using eqn (3) to fit the simulation MSD with the independently measured $D_T$ and $\mu$, the strength $D_A$ and the relaxation time $\tau$ of the active noise experienced by the passive tracer can be directly extracted.

3 Results and discussion

We first measure the MSD of the passive tracer particle in a semidilute active solution with the packing fraction of the microswimmers $\rho = 0.3$ for various trap stiffness $k$. Two representative MSD curves with $k a^2/\kT = 40$ and 120 are shown in Fig. 3(a). The MSD data can be well fitted to eqn (3) using $D_A$ and $\tau$ as fitting parameters, with $D_T \approx (0.47 \pm 0.02) kT/\tau_1$ and $\mu \approx (0.59 \pm 0.01)/\tau_1$ that are independently measured in simulations. Here, $D_T$ is obtained from the MSD of a passive tracer freely moving in a solution of inactive microswimmers (without activity, $F_A = 0$), and $\mu$ is quantified by the drift velocity of a free passive tracer $v_d$ under an externally applied force $F_0$ in the active bath. To properly determine $\mu$, the applied force is so small that the system is in the linear response regime, as demonstrated by the linear relation between $v_d$ and $F_0$ in Fig. 2. Note that, in the semidilute situation, the measured $D_T$ and $\mu$ significantly deviate from the Einstein relation $D_T = \mu kT$, as analyzed in the theory above. For comparison, we also consider a dilute active solution with the microswimmer packing fraction $\rho = 0.06$. The MSD of the passive particle can still be well fitted to eqn (3), as plotted in Fig. 3(c). In this case, the Einstein relation $D_T = \kT/\mu$ is maintained as expected, with $D_T \approx (0.88 \pm 0.04) kT/\tau_1$ and $\mu \approx (0.89 \pm 0.01)/\tau_1$, close to its thermal counterpart.

The quantities $D_A$ and $\tau$ obtained from the MSDs show a clear dependence on the trap stiffness $k$ in both semi-dilute and dilute active baths, as plotted in Fig. 3(b) and (d). The strength of the active fluctuations monotonically increases with $k$ for both packing fractions, while the relaxation time of the active noise exhibits a different dependence on $k$ for the semidilute and dilute active baths. The dependence of $D_A$ and $\tau$ on the external constraint unambiguously indicates that the active fluctuations experienced by a passive tracer are not an intrinsic property of the active bath, and external constraints must be considered when active noise exists.

The increase of $D_A$ with $k$ can be understood from the collision kinetics between the tracer and the active swimmers. One of the distinctive differences between collisions with passive and active particles is that the momentum change in collisions with passive particles depends only on the momenta before the collision, while additional momentum can be transferred to the tracer from the persistent motion of the self-propelling swimmer. The intensity of the persistent collisions with microswimmers, thus $D_A$, can be greatly influenced by the constraints imposed on the passive tracer. Briefly, for strong constraints, most of the driving force $F_A$ is transferred to the tracer, leading to a large $D_A$; while for weak constraints, the friction on the colliding swimmer (moving with the tracer at a relatively large velocity) offsets part of $F_A$ and weakens the collision intensity. This picture can be qualitatively formulated by implementing an approximate calculation based on microscopic collision processes. For simplicity, we only consider a head-on collision between the passive and active particles (i.e., the swimmer orientation parallel to the vector connecting the swimmer and tracer). Further, we assume that before the collision, the passive tracer rests at the trap center; and after the collision, the swimmer moves with the tracer for a duration of the orientational relaxation timescale of the
swimmer, \(\tau = \gamma_{\text{r}}/k_{\text{B}}T\). Disregarding the thermal stochastic force (only considering active collisions), the overdamped Langevin equation of the tracer particle reads \(\gamma_{\text{r}}r\tau = -kr + F_{\text{d}}\), which is obtained by noticing that \(F_{\text{d}} - \gamma_{\text{r}}r\) corresponds to the force exerted on the tracer by the swimmer. By solving this equation, we obtain the tracer trajectory

\[
r(t) = \frac{F_{\text{d}}}{k}\left[1 - \exp(-kt/\gamma_{\text{r}})\right],
\]

with \(\gamma = \gamma_{\text{r}} + \gamma_{\text{a}}\). The active stochastic force, \(\mathbf{\eta}^a/\mu\), arising from the persistent collisions between the swimmer and tracer is roughly proportional to \(F_{\text{d}} - \gamma_{\text{r}}r\). Hence, \(\langle \mathbf{\eta}^a(t) \mathbf{\eta}^a(\tau) \rangle = 2D_{\text{A}}/\tau_k\), which can be evaluated using eqn (4). With the equal-time correlation of the active noise \(\langle \mathbf{\eta}^a(t) \mathbf{\eta}^a(\tau) \rangle = 2D_{\text{A}}/\tau_k\), we obtain

\[
D_{\text{A}} \sim \frac{1}{2}\mu^2 F_{\text{d}}^2 \left[1 - \frac{2k}{\tau_k} \left[1 - \exp(-\tau_{m}/k/\gamma_{\text{r}})\right] + \frac{k^2}{2\tau_k^2}\left[1 - \exp(-2\tau_{m}/k/\gamma_{\text{r}})\right]\right],
\]

which monotonically increases with \(k\) and saturates at large \(k\), consistent with the simulation results in Fig. 3. These calculations do not consider the events of the tracer simultaneously colliding with multiple swimmers or the swimmer–tracer collision frequency.

The \(\tau_k\) dependence of the relaxation time of the active noise can be understood by considering non-head-on collisions between the tracer and the swimmers. For non-head-on collisions in dilute solutions, strong constraints prevent the tracer from disengaging from the colliding swimmer, which results in a more persistent collision and hence a longer \(\tau_{m}\). For non-head-on collisions of microswimmers around the passive tracer and the bath, the active noise is not an intrinsic property of the microswimmers, which can be understood by considering non-head-on collisions of microswimmers around the passive tracer and the bath and the persistent collisions from the active particles, respectively.

As plotted in Fig. 4(a) and (c), \(D_{\text{A}} + D_{\text{d}}/\mu\) is markedly higher than the thermal temperature, and increases with the trap stiffness until saturation at large \(k\). This trend can be qualitatively understood in terms of the \(k\) dependence of \(D_{\text{A}}\) discussed above, as \(D_{\text{d}}\) and \(\mu\) remain unchanged.

The second effective temperature \(E\) is obtained by directly measuring the average kinetic energy of the passive tracer, \(1/2M\langle V^2 \rangle\), in underdamped Brownian dynamics simulations. As plotted in Fig. 4(a) and (c), \(E\) decreases with the trap stiffness, which is qualitatively opposite to \((D_{\text{A}} + D_{\text{d}})/\mu\). The \(E\) dependence on \(k\), however, is relatively weak, with \(E\) only slightly higher than the thermal temperature. The explanation of this trend is straightforward. The tracer obtains additional kinetic energy from collisions with the microswimmers in the active bath. Consider a trapped passive tracer, its mean kinetic energy reads \(E = 1/2M\langle (V_0 + V_{\text{A}})^2 \rangle = k_{\text{B}}T + 1/2M\langle V_{\text{A}}^2 \rangle\), where \(V_0\) and \(V_{\text{A}}\) are the velocities contributed by the thermal bath and the persistent collisions from the active particles, respectively. In the present system, \(V_0\) and \(V_{\text{A}}\) are uncorrelated, and \(V_{\text{A}} \propto V_0\). The active contribution to the mean kinetic energy, \(E_{\text{A}}\), can be roughly estimated through eqn (4) as

\[
E_{\text{A}} \sim \frac{1}{2}M\langle V_{\text{A}}^2 \rangle \sim \frac{M}{2\tau_k} \int_0^{\infty} \langle r^2 \rangle dt = \frac{M F_{\text{d}}^2}{4\tau_k \gamma_{\text{r}}} \left[1 - \exp(-2\tau_{m}/k/\gamma_{\text{r}})\right],
\]

which monotonically decreases with \(k\) and saturates at large \(k\).
Fig. 4(b) and (d) plot the mean potential energy, $U$, of the confined passive tracer in active baths of different concentrations, as a function of trap stiffness. Similar to the kinetic energy, the potential energy $U$ also decreases monotonically with $k$, and remains above $k_b T$ for all the $k$ investigated. The range of $U$, however, is much greater than that of $E$. During the collisions between the tracer and the swimmers, the persistent driving force of the swimmer can displace the tracer from the trap center, which results in an additional potential energy for the tracer. Combined with the thermal bath contribution $k_b T$, the total mean potential energy of the tracer can be approximately calculated from eqn (4) as $U \sim k_b T + \frac{1}{\tau_r} \int_0^\infty \frac{k}{2} \bar{v}^2 \, dt = k_b T + \frac{F_d^2}{2k} - \frac{3F_d^2}{4k^2} \left[ 1 - \frac{4}{3} \exp(-\tau_r/k/\gamma) + \frac{1}{3} \exp(-2\tau_r/k/\gamma) \right]$, which decreases with $k$ and saturates at large $k$, in qualitative agreement with the simulations.

A more quantitative expression of the potential energy can be derived from eqn (3) by taking $t \to \infty$,

$$U = \frac{D_T}{\mu} + \frac{D_A}{\mu} \frac{1}{1 + \mu k \tau}$$  \hspace{1cm} (5)$$

The first term on the right side of eqn (5) is related to the thermal noise contribution that remains constant in a given system. However, $D_T/\mu$ generally does not equal $k_b T$, since $\mu$ contains the active friction. The second term depends on the stiffness coefficient not only through $k$ in the denominator, but also through both $D_A$ and $\tau$. The potential energy of the tracer particle can then be determined by eqn (5), using $D_T$, $\mu$, and $k$-dependent $D_A$ and $\tau$ obtained from simulations. Fig. 4(b) and (d) show that the theoretical values of $U$ (crosses) thus obtained agree perfectly with the measured potential energy in simulations (diamonds). On the other hand, when constant $D_A$ and $\tau$ are applied, the predictions of eqn (5) deviate significantly from the measured potential energy (not shown), which further confirms that the active noise experienced by a passive tracer depends sensitively on its external constraint.

4 Conclusion

Active noise provides us with an ideal framework to coarse grain an active bath. Using computer simulations and theoretical calculations, we here show that the active noise experienced by a harmonically trapped passive tracer in an active bath, as well as three related effective temperatures, depends sensitively on the external constraint imposed on the passive particle, which is fundamentally different from the equilibrium cases. This constraint dependence arises from the persistent collisions between the passive tracer and the active swimmers, which can be greatly impacted by the constraint strength. Our results unequivocally demonstrate that the active noise and effective temperatures are not intrinsic properties of active baths, and great care must be taken when applying these quantities in active systems. Our findings are experimentally verifiable by optically trapping a colloidal sphere in a bacterial solution.
